IBM Research

ABSTRACT
The study of complex activities such as scientific production and software development often require modeling connections among heterogeneous entities including people, institutions and artifacts. Despite numerous advances in algorithms and visualization techniques for understanding such social networks, the process of constructing network models and performing exploratory analysis remains difficult and time-consuming. In this paper we present Orion, a system for interactive modeling, transformation and visualization of network data. Orion’s interface enables the rapid manipulation of large graphs—including the specification of complex linking relationships—using simple drag-and-drop operations with desired node types. Orion maps these user interactions to statements in a declarative workflow language that incorporates both relational operators (e.g., selection, aggregation and joins) and network analytics (e.g., centrality measures). We demonstrate how these features enable analysts to flexibly construct and compare networks in domains such as online health communities, academic collaboration and distributed software development.

Keywords: social network analysis, data management, data transformation, graphs, visualization, end-user programming.

1 INTRODUCTION
As social network analysis has gained popularity, researchers have developed novel statistical techniques, visualization designs, and user interfaces to better support the complex tasks of making sense of large networks. However, many of these recent advances take the process of assembling a network model for granted. Much data that is collected for analysis, whether scraped from online data sources or tabulated using traditional surveys, is not inherently in the form of a network but instead a raw list of data points and their corresponding attributes. This requires analysts to extract their own model of a network from the raw data. But for many data sets, networks can be modeled in as many different ways as analysts have hypotheses. For instance, after collecting a database of online community data, analysts may wish to examine the relationships between community members to measure collaborative support, or the relationships between thread posts to measure the dissemination of information, or the relationships between communities as a whole to measure comparative community success. To analyze each of these scenarios, completely different network models need to be extracted from the original data.

Typically, refactoring network data into such various models requires custom code that can take analysts days or even weeks. While it is also possible to express most of the necessary operations as database queries, this requires defining a schema, loading the data, and then forming the correct SQL queries—including complex queries such as multi-table joins. Repeating this level of effort as new questions emerge may undermine the exploratory process and even dissuade some analysts from testing all hypotheses.

To address these issues, we introduce Orion, a system for interactive modeling, transformation and visualization of network data. While many visualization and data mining techniques have been proposed for social network analysis, to our knowledge Orion is unique in its support for the early stages of data transformation and assessment when forming network models from source data. Orion enables iterative, exploratory analysis by reducing hours of programming and transformation to a few minutes of interactive, graphical specification. We make the following contributions:

A unified model and workflow language for network data. We use relational data tables as our fundamental model and represent networks as edge tables over a domain of integer node indices. We chose this model to correspond to those used by analytic databases and scalable network analysis packages. Our workflow language provides both relational operators and graph analysis routines and enables the generation of reusable analysis scripts. The language supports a range of analysis tasks including network definition, filtering, aggregation, and statistics computation.

A graphical user interface for iterative network manipulation and visualization. Orion translates user interface actions, such as drag-and-drop and menu commands, into operations in the underlying workflow language. Orion also supports the specification of complex linking relationships. The system first constructs a graph model of links among table columns; a traversal algorithm then identifies all feasible linking paths defining networks for a set of user-selected node types. This approach simplifies the otherwise difficult process of specifying a series of relational join and aggregation operations. Once a network has been defined, Orion enables visual exploration using tabular, matrix and node-link views. Networks can also be exported for use in other analysis tools.

The rest of the paper is structured as follows. After reviewing prior work, we describe our data model and present the Orion interface. Next, we discuss our enabling algorithms for network extraction and describe our workflow language. As a preliminary evaluation of Orion, we demonstrate its use in case studies in online health communities, academic collaboration and distributed software development. We then discuss future work and conclude.

2 RELATED WORK
Orion draws on related work in graph visualization, analysis tools, and data management. We discuss selected relevant projects below.

2.1 Graph Visualization Techniques
Researchers have devised a variety of visualization techniques for networks [16]. Two common representations used in social network analysis are node-link diagrams (typically using force-directed placement) and adjacency matrix views [8]. Hybrids of the two have also been proposed [14, 15]. These approaches organize elements according to the linkage structure of the graph.

An alternative approach is to plot network data according to the attributes of the nodes (e.g., [28, 33]), as in a scatter plot or so-called “semantic substrates” [28]. Network links can then be drawn between nodes. This approach is well-suited for assessing potential correlations between node attributes and network structure.

In a related vein, PaperLens [23] uses multiple coordinated views of node attributes to explore publication databases. The NetLens system [22] generalizes this approach to support networks that fit a
“content-actor” data model, i.e., bipartite networks such as publications and authors. In contrast, Orion supports an arbitrary number of linking relationships both within and between data tables.

Others have researched means of dealing with large graphs in excess of tens of thousands of nodes. Common strategies include filtering and aggregation. van Ham and Perer [32] introduce a degree-of-interest function [6] that reduces a graph to a small connected subset of nodes based on a set of loci (e.g., search results). PivotGraph [33] and Honeycomb [9] aggregate networks by “rolling up” edges according to shared node attributes; an analyst can collapse a social network of corporate employees to show the summed connection strengths between workers’ geographic locations. ManyNets [5] enable comparison among multiple networks using a tabular view of summary graph statistics. If desired, users can still view standard (albeit less scalable) node-link diagrams on demand.

Orion draws on this prior work: it provides both node-link and matrix visualizations and supports network aggregation based on node attributes. However, with the sole exception of NetLens [22], each of the above systems assume a well-defined network is given as input to the tool. None of these tools help the user define and assess a variety of network models derived from arbitrary data tables.

2.2 Network Analysis Tools

Recent years have seen a proliferation of network analysis tools. Many of these tools combine visualization and statistics within an interactive environment [1, 7, 25, 27, 29]. Others are programming libraries [18, 19, 24] or menu-driven interfaces [3, 31] that provide access to analysis algorithms. While these tools support data import from common file formats (e.g., GraphML) and external data services (e.g., Twitter or Facebook), they do little to facilitate the flexible construction of network models from arbitrary data tables. Orion is not intended as a replacement for these systems; rather, it is designed to assist the unsupported early stages of network analysis. In the process, it enables the use of these downstream tools.

2.3 Managing Graph Data

Another domain of related work is graph data management. Database researchers [2, 10] have developed storage strategies and query languages [10] for large networks. Similarly, a number of commercial systems—including neo4j, InfiniteGraph, AllegroGraph, DEX, OrientDB, and sones/GraphDB—are now available. These systems facilitate storage, indexing, and querying of large graphs, but with goals different from Orion. Representative applications include managing social network web sites and querying motifs in biological networks. Orion instead focuses on the construction and assessment of network models from source data.

2.4 Interactive Data Transformation and Querying

Orion focuses on transforming data to create network models; other systems similarly assist early stages of data cleaning and reformatting. Google Refine [17] and Data Wrangler [20] enable analysts to reformat input data sets and correct data errors prior to analysis. D-Dupe [21] assists the process of finding and resolving duplicates within a data set. Any of these tools might be used to prepare data tables prior to network modeling with Orion. Similar to Wrangler, Orion produces as output not only data, but also a declarative transformation script that can be reapplied to new data and inspected to review data provenance. In this light, Orion can also be understood as an end-user programming tool for network manipulation.

Orion was particularly influenced by the Polaris system [30], now commercialized as Tableau. Polaris maps drag-and-drop operations of data variables into a formal algebra from which both database queries and resulting visualizations can be derived. One key insight from this work is the value of deeply coupling visualization tools with rich facilities for data transformation. Orion similarly provides a user interface in which user actions are mapped to statements in an underlying data transformation language. While Polaris enables filtering and aggregation operations over a single data table, Orion instead enables manipulation of multiple tables, including linking relationships realized as relational joins.

3 Data Model

A variety of data models exist for handling graph data; common structures include adjacency lists and adjacency matrices. However, these representations alone are insufficient for network analytics, as in many cases networks must be derived from a prior data source permitting a number of models and parameterizations. As a simple example, a social network extracted from an email archive might include links only between senders and recipients, or might include links among all co-recipients.

Prior research on visualization toolkits has noted the value of representing networks as relational tables [11]: each row represents an edge in the graph, and columns contain source and target node values among other edge attributes. This format provides a sparse representation of the network, enables easy querying of attributes, and supports efficient edge iteration. On the other hand, this format is inefficient for path following and is thus ill-suited for many graph algorithms. As a result, we adopt a hybrid data model in Orion.

We use relational data tables as our base representation. Tables can represent individual node types or linking relationships. At times, node types may be implicit within the attributes of a table; Orion provides methods to promote these values to their own table. Networks can be inferred from the foreign key relations among tables. This design allows us to support auxiliary node types and linking relations while facilitating integration with relational databases. Once a specific linking relationship has been chosen (as described in subsequent sections), Orion models the network using a specialized edge table format. Source and target columns represent incident nodes using zero-based integer indices. For efficient processing, these indices default to the row index in the corresponding node table. This scheme works well for edges involving a single node table, but leads to index collisions among different tables. To ensure distinct keys we bias the indices for a given table by the total size of any previous tables. The mapping from node tables to index ranges is stored as metadata for the edge table.

Some graph analysis routines, such as force-directed layout or clustering coefficient calculation, can be performed by simply iterating over edges. However, other methods—including shortest path and betweenness centrality algorithms—must traverse the graph by following paths. Accordingly, our edge tables support the construction and caching of adjacency lists, represented as an array of sorted integer arrays for in-links, out-links or both.

We have found this integer-based representation provides multiple benefits. In particular, it aids rapid access of associated node data via index-based table lookups and facilitates the creation of efficient network analysis routines. Representing nodes as zero-based integers enables the use of simple arrays to keep state within graph algorithms, avoiding the overhead of associative data structures.

Our data model, like the rest of Orion, is implemented in the Java programming language. We have implemented our own data structures and processing routines, but our data model was intentionally chosen to correspond to those used by modern analytic databases and scalable network analysis packages (e.g., [24]). In future work, we want to exploit this correspondence to implement our workflows on massively scalable platforms. We use relational operators for as much of our workflow as possible so that we can later leverage shared-nothing parallel databases. That said, we will show shortly that our own implementation already scales to networks involving millions of elements, and so supports a broad class of data sets.
Figure 1: The Orion User Interface, consisting of (a) a schema viewer for manipulating data tables and (b) a linker interface for creating network models. Analysts drag-and-drop desired node types to the linker and Orion responds with (c) a table of possible linking paths. The (d) preview display shows the resulting network data. Analysts can also specify (e) aggregation, (f) filtering, and (g) splitting (subdivision) criteria.

4 THE ORION USER INTERFACE

With the Orion user interface, analysts can import source data from multiple formats, specify a variety of network models, compute statistics, and visualize the results. Analysts can then export either the resulting data or a declarative script defining the transformation workflow. In this section, we first describe the design of the Orion interface through a concrete usage scenario. We then provide more detailed descriptions of Orion’s user interface components.

4.1 Usage Scenario

Consider the real-world example of a researcher studying online health communities organized around medical conditions (e.g., asthma, lupus, lyme disease, etc). Driving questions include: How do community dynamics and structure vary across conditions? Can we gain new insights from the co-occurrence of symptoms and conditions? To explore these questions, our analyst collected over 3 million discussion posts by crawling MedHelp.org, a public online health site. The initial database consists of a single table where each row represents a post on the site. Table columns include a forum (community) name, the user name of the poster, the post date, the title of the discussion thread, and the post text.

From this data, the analyst would like to analyze the social networks of the individual communities. She begins by importing the data table (a large CSV file) into Orion. The table and its columns are displayed in the Schema Viewer in Figure 1a. Currently, these entities reside implicitly as values within the table. The analyst right-clicks the username field and selects “Promote” in the resulting context menu. This operation causes all username values to be extracted from the table: a new table is constructed with one row for each unique user and the username field in the original table is replaced with a foreign key referencing the new table. As the analyst wishes to model a social network based on co-participation within a discussion thread, she similarly promotes the thread_id field as an entity of interest.

The analyst would now like to construct a social network among users. She drags the id field (the primary key) from the username table and drops it on the Linker interface in the center of the Orion window (Figure 1b). The interface allows analysts to specify desired source and target node types. In response, Orion calculates all feasible network definitions involving username entities as nodes (Figure 1c). In this case, there is only one feasible result: linking users by shared threads. Should the analyst wish to consider alternatives, she could promote other entities (e.g., individual forums).

When the analyst clicks the check box to include the linking path, Orion responds by showing a preview of the resulting graph (Figure 1d). Orion previews include both a list of tables that will be generated, and an inspector for individual table values. For now the analyst would like to limit her exploration to a single community. She drags the forum field from the Schema Viewer to the Filter region of the Linker; she then selects the “Asthma” forum using the resulting search box (Figure 1f). The preview updates in turn. Satisfied, the analyst clicks the “Create Network” button to add the network to the data set; the Schema Viewer updates with a new edge table containing links between all posters to the “Asthma” forum who have posted to the same thread; by default, edge weights indicate the number of shared threads between two users.

By right-clicking the “Asthma” edge table, the analyst reveals additional options. She can choose to visualize the network using both matrix and node-link diagrams. In a matrix overview (Figure 2a), the disjoint structure of the community becomes evident which suggests that newcomers arrive into the community, ask a question, and it gets handled by one of a handful of leaders. This also suggests that the community may be more of an answer mill rather than a place of prolonged discussion. The analyst can dig deeper by filtering the visualization to only show a highly active cluster and pivots to a node-link visualization (Figure 2b). Here, with nodes sized by their post count and colored according to their betweenness centrality, the analyst can focus on specific nodes of interest for further analysis.
Individual tables can be inspected and visualized using bar or scatter plot charts. Each visualization also supports interactive filtering controls. After filtering the graph to highlight interesting patterns, the analyst can save the filtered edge table as an additional entry in the Schema Viewer. The analyst can also compute statistics, including node degrees, betweenness centrality and clustering coefficients. Applying a statistic adds additional columns to implicated edge and/or node tables.

Now the analyst would like to assess the effects of using a different network model. The current model includes edges connecting all posters to the same thread. What happens if instead thread respondents are connected only to the thread initiator? The analyst follows the same modeling path as before, but this time adds a join predicate: she right-clicks the linking path of the network and chooses to filter how the $\text{ohc}$ table is linked to itself. In this particular data, a poster has a post_id of 0 if they initiated the thread and a post_id greater than 0 if they responded to the thread. As these data characteristics are specific to this particular community data, the analyst enters a customized formula in the resulting dialog:

$$\text{INT1}('\text{post_id}') \neq 0 \land \text{INT2}('\text{post_id}') > 0$$

The formula ensures that the source node always corresponds to the thread initiator and that the target node is a respondent. The analyst creates this network, computes betweenness centrality values, compares values for the two models in a scatter plot (Figure 2c) and notes a high degree of correlation. She decides to proceed with the simpler model connecting only initiators to respondents.

The analyst would now like to start comparing the various health communities. She revisits her previous steps, but instead of filtering the forum field, she drags it to the Split region. The preview display then shows entries for multiple networks – one for each forum. Upon completion, these networks are grouped together within a subtree of the Schema Viewer. Context menus for the grouping element enables batch invocation of statistics for all contained networks (see Figure 7 for an example). The analyst can now continue analyzing the diverse characteristics of health communities.

## 4.2 User Interface Design

The previous scenario illustrates a subset of the modeling and visualization functionality supported by Orion. We now describe the user interface components in more detail. Along the way, we outline additional functionality, such as the ability to merge multiple sets of edges and construct “roll-up” graphs via node aggregation.

### 4.2.1 Schema Viewer

The Schema Viewer (Figure 1a) provides an overview of all data tables in the current data set and supports data manipulation. Source data tables and generated edge tables are indicated by icons. Table attributes are displayed using icons indicating their data type, with special annotations for primary and foreign key fields. Context menus enable analysts to rename and remove both tables and columns, create derived columns using an expression language, specify primary keys, and promote values in one or more columns to new node tables. Analysts can also access statistics and visualization options via context menus. Drag-and-drop interactions allow analysts to specify foreign key relations (by dragging a field on to a primary key with a matching type), import data (by dragging external data files from the operating system), and querying for network models (by dragging fields to the Linker interface).

#### 4.2.2 Link Specification

The Linker interface (Figure 1b) is the primary means of defining networks. Analysts start by dragging desired node types to fields for source and target nodes. Orion responds by computing the possible linking paths between the source and target nodes and displays the results in a table. Users can select the resulting paths to include those edges within the resulting network model.

**Filtering.** Analysts can drag-and-drop fields to specify filtering criteria (Figure 1f). Filters can be created for any table involved in the network. Orion generates dynamic query widgets—selection lists and range sliders—based on the data type. Corresponding predicates are then applied during network construction to limit the nodes and edges included in the final graph. In addition to single table predicates, analysts can specify filtering criteria directly on joins. Filterable joins are presented in a context menu when an analyst right clicks a linking path. Currently, Orion only supports user-defined join predicates specified as Java code statements.

**Splitting.** An alternative to filtering is to split a network into a collection of subgraphs. Examples include inspecting time slices and splitting on categorical variables (e.g., health forums). Orion supports splitting by categorical variables or using window functions over quantitative variables (see Figure 7). Of course, not all such splits are useful; naively splitting on a node’s primary key results in a collection of singleton graphs. In this special case, Orion instead interprets the split as a request for subgraphs centered at each node and provides a graph distance control. Analysts can extract all nodes and edges within a specified graph distance to extract egocentric networks. Networks generated by splitting appear as grouped collections that support batch operations.

**Rollup.** When specifying desired node types via drag-and-drop, typically the primary key of a node table is used. If analysts instead drag-and-drop a non-key field, an aggregated network will be constructed that uses the unique field values as individual nodes (c.f., PivotGraph [33]). The underlying nodes are grouped according to the requested field; edges between groups are tallied to provide an aggregate representation of the underlying graph.

**Multiple Edge Sets.** By selecting multiple linking paths, Orion allows analysts to construct networks with multiple edge sets.
When multiple paths are selected, the linking interface enables controls for choosing an aggregate function for merging edge sets (Figure 1e); options include basic logical (or, and) and arithmetic (count, sum, product) operations. For arithmetic operations, analysts can also provide numerical weights for each edge set.

*Preview & Confirmation.* As analysts manipulate settings within the linker display, a preview panel updates in response (Figure 1d). Analysts can review the number and size of all tables generated, and inspect the values of individual tables. Once an analyst is satisfied with the linking definition, they can click the ‘Add Network’ button to add all resulting tables to the schema viewer.

### 4.2.3 Visualization

Orion also supports visualizations: table displays, basic data graphics (bar and scatterplot charts), node-link diagrams, and matrix views. Visualizations are shwon in a separate pane. Different visualization types are accessible via tabbed panels. These windows include a schema viewer containing only the data tables implicated in the current visualization. Similar to tools such as Tableau and Spotfire, analysts can parameterize the display and perform visual analysis using filtering, sorting, zooming, and visual encoding controls. To support a variety of visualizations, Orion uses the Java implementation of the Protovis specification language [12].

### 5 NETWORK DEFINITION AND EXTRACTION

Having introduced the Orion interface, we now discuss some of the underlying algorithms enabling interactive network modeling. While relational tables provide a flexible model for representing data, network extraction involves creating linking queries that regularly include one or more join operations. As a result, defining networks via a query language such as SQL can be tedious and error-prone. To simplify the process, Orion models the connections among data tables and analysts request networks simply by specifying the desired node types. The system then enumerates the possible network definitions, from which an analyst can choose.

We describe the steps of this process in the following subsections. First, we construct a linking graph that models the foreign key relations among tables. In response to user queries (i.e., desired node types), we then run a search algorithm over this graph to identify valid linking paths. Linking paths are then translated into relational algebra statements for extracting network edge tables.

#### 5.1 Linking Graph Construction

To aid network definition, Orion builds a linking graph; a data structure that supports user queries over possible network models. Nodes within a linking graph correspond to data table fields (columns); primary key fields are assumed to represent a specific node type. Edges in the graph represent relationships among fields (e.g., foreign key references) that might be used to define a network among node types. Given input schemas for a set of data tables, Orion constructs a directed graph containing three types of edges:

1. **Key reference** (R) edges link all primary and foreign keys representing the same node type.
2. **Intra-table** (T) edges link all foreign keys within a table. The edges represent potential linking paths between node types.
3. **Conjugate** (C) edges link a foreign key of one node type to a primary key of a different node type if and only if the table containing F has an additional foreign key that references P.

While the first two edge types are straightforward, conjugate edges merit further explanation. These edges represent paths in which one can join a linking table with itself to form a bipartite graph—a process analogous to multiplying a bipartite adjacency matrix by its transpose. Key reference (R) and intra-table edges merit further explanation. These edges represent paths in which one can join a linking table with itself to form a bipartite graph—a process analogous to multiplying a bipartite adjacency matrix by its transpose.
Algorithm 1 FindPaths(source, target):

maxOccurrences ← source = target * 3 : 1
paths ← {}
queue ← new Queue([source])
while queue is not empty do
    path ← dequeue(queue)
    len ← length(path)
    t ← len < 2 ? null : previous(path)
    u ← current(path)
    for all e ∈ edges(u) do
        if sameBase(u, v)
            a ← sameBaseBase(t, u, v) ∧ (len > 2 ∨ ¬sameTable(u, v))
            c ← type(e) ≠ R ∧ sameTable(t, u, v)
            d ← type(e) = C ∧ ¬(sameTable(t, u) ∧ sameBase(t, v))
            if ¬(a ∨ b ∨ c ∨ d) then
                newPath ← append(copy(path), v)
                if v ≠ target then
                    enqueue(queue, newPath)
                end if
                if reverse(newPath) ∉ paths then
                    paths ← paths ∪ {newPath}
                end if
            end if
        end if
    end for
end while
return path

5.2 Linking Path Search

Given a linking graph and desired source and target fields (node table primary keys), Orion searches the graph to identify valid linking paths. These paths can be translated into relational algebra statements (e.g., projections and joins) to create a network edge table.

Orion’s path-finding method (Algorithm 1) performs a breadth-first traversal starting from the source field. The traversal algorithm allows repeated visits, but greedily prunes the search at each step by testing the validity of candidate path segments. For a given path segment path, we denote the most recently added field by u, the previously added field by t, and a newly encountered candidate field by v. All fields have a corresponding base field indicating the node type: primary key fields reference themselves, while foreign key fields reference a primary key. With these definitions in place, valid paths are defined by the following conditions, which roughly correspond to the boolean variables a, b, c, d within Algorithm 1:

1. Excluding source and target fields, paths can not contain the same base more than twice.
2. The same base field can not occur three times consecutively unless u and v are in the same table.
3. Three consecutive fields can not be from the same table, unless the third field is reached by a key reference edge (R).
4. A field reached through a conjugate edge (C) can not be added to a path unless (a) t and u are in the same table and (b) t and v share the same base field, which differs from that of u.

The algorithm returns a set of valid linking paths with which an analyst can define a network model. To simplify the results, Orion sorts the returned paths such that shorter paths with less variation in base field types are listed first.

5.3 Network Extraction

Once an analyst has selected a set of desired linking paths, Orion translates these paths into relational algebra statements that when evaluated provide a network edge table. Figure 4 provides examples of input queries and the resulting linking paths and relational algebra statements (using the data and linking graph in Figure 3).

Mapping paths to relational algebra is straightforward. In most cases, each pair of fields (ignoring source and target fields) maps to two columns of the same table, with adjacent pairs related by an equijoin on the shared inner field. Special cases include conjugate edges, for which an encountered pair is instead joined against itself, and “self-edges” within a table that result in an odd number of path elements (e.g., tree data with paths of the form T F Φ T F Φ T).

When an analyst selects a network definition, Orion executes the resulting queries and constructs an edge table with integer node indices (§3). Orion similarly turns filtering criteria specified in the user interface into relational selection predicates that are incorporated into the queries. If an analyst selects multiple linking paths, Orion will construct multiple edge tables. Orion then forms the union of these edge tables; analysts can further specify aggregation functions in the Orion user interface to control if and how multiple edge sets should be merged.

6 Orion Workflow Operators

In addition to transforming data, one goal of Orion is to enable the construction of editable and reusable analysis workflows. These workflows are realized in a declarative language incorporating both relational operators and network statistics. By mapping user interface actions into statements in this language, Orion supports not only data manipulation and visualization, but can also export reusable scripts that keep a record of data provenance. In this section we describe the operations supported by our language and how they can be used to model and analyze network data.

Each Orion workflow task is an operator accepting one or more named parameters. These operators modify a data set: a collection of named tables. A workflow is simply a sequence of tasks. Figure 5 shows an example workflow for the case study in §7.1. Orion externally represents workflows using a simple XML format.

6.1 Data Import and Export

Orion’s input / output operators read in data from different sources and write results in a variety of formats. The read operator imports data tables from external sources such as delimited text files (e.g., comma- or tab-separated values), relational databases, and GraphML or Dot (GraphViz) network files. Network files are translated into tables, typically one node table and one edge table. For delimited text files, Orion infers column data types based on their contents. The write operator writes either individual tables or extracted networks to a database or files in these same formats.

6.2 Schema Modification

Orion includes a handful of operators for modifying table schemas. The rename operator renames tables or individual columns. The key operator indicates that a column serves as a primary key, while the references operator assigns foreign key relations. Foreign key relations are particularly important, as they are used as the basis for determining feasible linking paths. While tables pulled from relational databases often have the appropriate key relations defined in their schemas, data in common formats such as CSV regularly lack this metadata. To add this metadata, our key finding algorithm (§5.1.1) generates a sequence of key and references statements.

6.3 Table Transformation

To aid the creation of network models, Orion provides operators for manipulating single tables. The remove operator simply drops a column or table. The derive operator allows analysts to create new columns by writing a user-defined function over existing columns. Orion currently accepts user-defined functions as snippets of Java code that are dynamically compiled at run-time.
6.3.1 Ranking Table Rows
The rank operator adds a new column containing rank-ordered integer indices. Rank statements must include sorting criteria: one or more fields to sort in ascending or descending order. The sort order determines a set of non-repeating indices. Statements can also take group-by fields: each group is then rank-ordered separately. The rank operator can be used to create indices enabling nuanced join predicates (e.g., the post_id field used in the scenario of §4.1).

6.3.2 Promoting Column Values to Node Tables
Tabular data often contains implicit linking relationships via values embedded in a column. For example, a single table of research grant awards might contain fields for a principal investigator (PI), a co-PI, and the institutions of each. From this data one may wish to form social networks of researchers and/or institutions. To help model such networks explicitly, Orion provides the promote operator. Given one or more field names, the promote operator first identifies and counts all distinct values in those columns and then populates a new table with the schema (id, value, count). Values in the output table are replaced with foreign key references to the new “promoted” table. This operation allows analysts to extract implicit node types into explicit node tables. Returning to the grants example, an analyst might promote the PI and co-PI columns to create a new node table for people; the original table now serves as a linking table defining a network among people nodes.

6.4 Network Modeling
At the core of the Orion language are network creation operators.

6.4.1 Network Definition
Given a set of linking paths as input, the link operator extracts a network (edge table) according to the process described in Section 5. All input linking paths must have the same starting and ending fields. If multiple linking paths are provided, the link operator will construct a single edge table that is the union of the per-path edge tables. The resulting table includes a path_id column indicating which linking path generated a link. If an optional aggregation parameter is provided, the operator will generate a final edge table by applying an aggregate function over a group-by of the source and target columns; the aggregate values then become the edge weights.

The link operator also accepts optional projection and filtering parameters. Projection parameters consist of node or linking table columns to include across joins (as if included in a SQL SELECT clause). Filter parameters are name-value pairs of table names and predicate functions. Both single-table predicates (for filtering either node or linking tables) and two-table predicates (for join predicates on linked tables) are accepted. The link operator also accepts boolean parameters for suppressing self-links in unipartite graphs and for ensuring that only distinct edges are considered in linking tables. The latter enforces pre-aggregation of linking tables.

6.4.2 Sub-Network Extraction
Once a network has been created, Orion provides operators for extracting sub-graphs. For example, an analyst may want to compare time-slices of an evolving network or various ego-centric networks extracted from a larger social graph. The filter operator creates a filtered edge table based on a set of edge and node predicates. Edges are removed if a node predicate returns false for any incident node.

Given a set of “focus” nodes, the subgraph operator returns a subgraph containing all edges within a specified minimum distance. Orion measures graph distance by counting hops or summing edge weights. In the future, we plan to also support the degree-of-interest extraction method introduced by van Ham and Perer [32].

Orion also provides iterators that enable repeated invocation of an operator over a sequence of parameter settings. Iterators are useful for performing batch operations, such as repeated filtering

Figure 5: An example Orion workflow definition for the online health case study in §7.1. Here the workflow is shown as Java code; workflows can also be persisted using a simple XML format.

or subgraph extraction. Iterators can implement split operations to segment networks according to categorical or numerical fields. For numerical data columns, analysts can choose to split a network using a sliding window (e.g., to create separate time slices of a network) or an anchored window (e.g., to show the evolution of a network over time) while specifying the bounds of interest. Iterators also enable batch statistics calculation (see §6.5).

6.4.3 Network Aggregation
At times an analyst will be more interested in the aggregate properties of a graph than in leaf-node details; given a social network, she may wish to view the aggregate connections among genders or cities. The rollup operator aggregates edges according to specified properties of the nodes (c.f., [33, 9]). The rollup operator generates an aggregate edge table and node tables for the node attributes.

6.5 Network Analysis
Orion additionally provides network analysis algorithms. The stats operator computes one or more statistics of a network and stores the resulting values in the corresponding node or edge tables. The statistics operator is modular, allowing user-defined functions to be added to the workflow language. Currently these functions must be written in the Java programming language and conform to a provided interface definition. Supported statistics include in-degree, out-degree, betweenness centrality, eigenvector centrality, clustering coefficient, edge weight asymmetry, edge weight deviance, community identification, and linkage-based sorting.

While many of these metrics are common to social network analysis, a few deserve special mention. The edge weight asymmetry and deviance measures are inspired by van Ham et al’s Honeycomb [9] system. The former is simply the logged ratio of edge weights between corresponding anti-parallel edges in a directed graph. The latter calculates the amount an edge weight deviates from the expected value if one assumes a uniform random distribution of total weight across the cells of the adjacency matrix. Deviance can help identify edges with unexpectedly strong or weak strengths, particularly in dense aggregated networks.

Community identification is performed via a greedy hierarchical clustering optimizing Newman’s modularity metric [26]. Linkage-based sorting provides an integer sort order of nodes that attempts to minimize the distance among connected nodes. We approximate this objective by seriating the nodes using the cluster tree constructed by the community identification algorithm (c.f., [34]). The resulting ordering is particularly useful for visualization purposes, such as permuting the rows and columns of an adjacency matrix diagram to reveal clusters (c.f., [14]).
The layout operator is similar to the stats operator, but instead computes spatial coordinates for subsequent layout in a visualization. This operator currently supports force-directed layout only.

6.6 Summary
In summary, the transformations supported by Orion are realized in a declarative workflow language. Saved Orion sessions are simply XML-serialized versions of this workflow, and so can easily be edited or reviewed directly in a text editor. While the Orion interface enables rapid specification of these workflows, we have also found that programmatic use of the workflow language (as in Figure 5) has greatly aided data analysis in our research groups.

7 Case Studies
We now present a collection of case studies illustrating how Orion has been applied to conduct network analyses in multiple domains.

7.1 Online Health Communities
The scenario in §4.1 introduced an analysis of online health communities. In addition to comparing the social networks of individual forums, our collaborating analyst is also interested in exploring the connections between communities. Might cross-posting behavior provide insights into the comorbidity of medical conditions?

To assess such questions, the analyst generates a network in which the nodes correspond to discussion forums and edge weights indicate the number of distinct users who have posted in both forums. To construct this network with Orion, the analyst promotes both the username and forum fields to node tables. The analyst then requests a network with forum nodes as both the source and target. Orion suggests the desired result: linking forums by shared users. The analyst then runs the edge weight deviance statistic to calculate the degree to which edge weights vary from the expected value (assuming a uniform random distribution). The resulting matrix diagram is shown in Figure 6, with cells colored by deviance.

By inspecting both this matrix view and the sorted edge table, the analyst has flagged a number of unexpected connections. Some connections appear to indicate possible data errors; for example, the hearing loss forum has unexpectedly strong connections to many other forums. Other strong connections indicate interesting co-occurrences (e.g., cold/flu and stress, ear/nose/throat problems and heart disease) or common misdiagnoses (e.g., lupus and lyme disease). Orion has enabled her to make these observations in a matter of minutes. The analyst is now following up on these results, for example by correlating them with external comorbidity data.

7.2 Academic Production and Collaboration
We are also using Orion to explore academic production and collaboration networks; for example, §5.1 discusses data extracted from the ACM Digital Library. To inspect the career progress of computer scientists, we use Orion to construct a social network based on co-publication. Using Orion’s subgraph extraction facilities (Figure 7), we define social networks over increasing periods of time (e.g., first all publications up to 2000, then 2001, etc). We then batch compute betweenness centrality scores for each extracted network. As Orion enables easy data export, we subsequently loaded the data into Tableau for further analysis, leading to the plot in Figure 8.

Orion’s flexibility also enables assessment of other models. For example, we have constructed the network of all researchers who have published in the same venue (by promoting and linking on the publication venue) within the same year (by specifying a join predicate enforcing matching years).

The ACM publication data contributes to a larger analysis initiative with social scientists at the first author’s university. The scientists are studying academic collaboration and have collected multiple data sets indicating links among university faculty. In addition to publication databases, the data include department and PhD committee memberships and co-PI relations on grants. These heterogeneous edge sets can be combined and weighted in any number
of ways to form a collapsed network. We are using Orion’s edge aggregation features to create and compare network models built from heterogeneous linking data.

7.3 Software Development on GitHub

Finally, we have used Orion in collaboration with computer scientists studying global development patterns in open-source software. The data under investigation comes from GitHub, a web service that hosts open-source projects. Using the GitHub web API, the researchers have collected over 1,000,000 million commits and 500,000 explicit “follower” connections among roughly 50,000 users. In addition, each user’s location has been geocoder according to a self-reported location string and then mapped to near-by major metropolitan areas (see Heller et al [13] for more details).

Using Orion, we can quickly generate and analyze networks extracted from this data. For example, we have constructed social networks based on commit history: a link is included between two users A and B if B makes a commit to the same repository immediately after A. We can specify this network in Orion by linking users via a table of commits. We have as input two tables: one for users and another for commits. The commit table includes the date, project name, and the user (as a foreign key). First we promote the project (repository) name to its own table, then link users according to a shared repository. We limit links to temporally adjacent commits by first applying a rank operation based on the commit date, and then adding a join predicate that ensures that only adjacent ranks are included in the resulting network.

We can also construct networks of “who follows whom” by linking users using a table of extracted follower relations. By requesting the user location attribute as a node type (rather than the user id), we construct an aggregated graph among major cities, with edge weights indicating the number of connections between users in those cities. We can then apply edge weight asymmetry and deviance statistics to examine differences among various locales. Figure 9 shows selected matrix views from this analysis (originally published in [13]). For example, in Fig. 9c we see that Paris and Tokyo each have many fewer incoming “followed” links than would be expected if links were assigned randomly, and that San Francisco consistently receives a surplus of “followed” links. While these particular images have been stylized for publication using Protovis [4], the underlying analysis can be performed completely within Orion.

8 Conclusion and Future Work

This paper introduces Orion, a system for interactive modeling, transformation, and visualization of network data. By providing a unified model, workflow language, and graphical user interface for iterative network manipulation, the construction and comparison of networks empower analysts to be more exploratory and flexible in their analysis. Through case studies involving online health communities, academic collaboration networks, and global software development, we demonstrate that Orion effectively supports the visual analysis of multidimensional heterogeneous networks.

As analysts gain the flexibility to create new models and transformations of network data with Orion, a critical need arises for better methods to preview and compare the constructed networks. While Orion provides some initial capabilities to support these tasks, we believe providing even more sophisticated visual and statistical techniques to summarize the similarities, differences, trends, and outliers of the resulting networks is an area ripe for future research. Additionally, while Orion provides great power for analysts to model networks that match their hypotheses, the vast number of possibilities to construct a network may seem daunting. Future work includes providing users with smarter suggestions to help uncover networks models with interesting and meaningful patterns.
